Abstract

Computer simulations of beam transport in the Scorpius injector were performed using the particle-in-cell computer code LSP. The simulations were used to predict spot size growth due to electron stimulated emission of ions from beam spill on the anode stalk and the entrance transport region [1, 2].

The Injector

The Scorpius injector is being designed to provide multi-pulse capabilities for flash-radiography applications at the U1a Facility. Forty-two IVA cells will be driven by solid state pulse power and supply a 2 Mega-volt electric potential across the A-K gap in a 1:1 push-pull ratio. The 2 MeV electron beam will have a current of 1.5 kilo-amps with expected rise- and fall-times in the 15 to 25 nanosecond range.

A smooth, well controlled logistics function was initially used in the beam transport simulations, however it was decided that a measured waveform from the TM-05 pulser would have rise- and fall-times that will be more representative of the waveform from the final pulser design. The TM-05 waveform shown in Figure 1 was modified as follows:

- The steady-state emission time was reduced from 120 nanoseconds to 50 nanoseconds.
- We assumed the energy variation during steady-state will be reduced as both technical maturation and our understanding of pulse modulation continue. Because of this assumption, the top of the measured pulse was flattened.

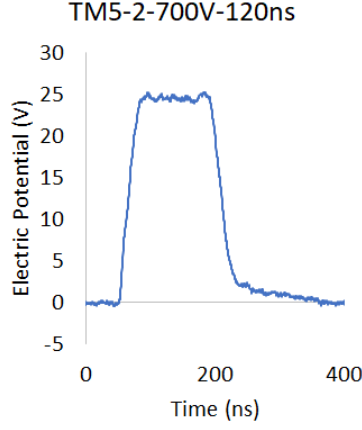

Figure 1: Measured TM-05 waveform from file TM5-2-700V-120ns-4pulse-500nsPeriod-Vpulser used to generate the waveform in Figure 2.

- The pulse was repeated to create four pulses separated by 200 ns.
- Figure 2 shows the final result.

The distance from the cathode face to the first accelerator cell gap was 8.8 meters, and the magnetic transport fields were tuned to transport the steady-state electron beam to the accelerator. The space charge limited emission results in the head and tail of the electron beam having lower energy and lower current than that of the steady-state portion of the beam, which makes the head and tail intrinsically mismatched and leads to beam spill on the anode stalk and beam Entrance Transport Region (ETR). Figure 3 shows the transport and corresponding beam spill of the electrons during the rise of the beam pulse and the beam transport during the steady state (matched) portion of the beam pulse.

The solid line in Figure 4 shows the beam current at the cathode ($z = 0$), while the dashed line shows the beam current at $z = 724$ centimeters downstream from the cathode. The difference between the two plots is a result of the beam spill.

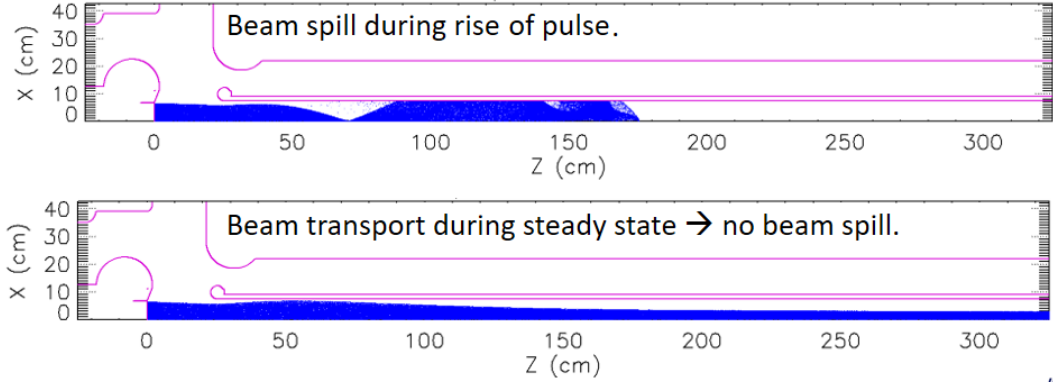

Figure 3: **Top** - Beam transport of the head of the electron beam, which has lower energies and lower currents compared to the steady state portion of the beam. **Bottom** - Beam transport of the 1.5 kA, 2 MeV (steady-state) the electron beam.

Stimulated Emission in LSP

LSP has the capability to simulate electron stimulated emission of ions from a surface. As with any computer simulation, there are limitations. Although the stimulated emission cross-section is dependent on the energy of the incident electron, the computer model only accepted a single, user entered value. Rudd's model [3] provided a theoretical calculation of the energy dependent cross-sections, and an approximate fit to Rudd's model provided an easy to use estimate of the theory. The number of electrons per energy bin were extracted and then converted to the number of electrons per cross-section bin. The average cross-section was found to be $7.1 \times 10^{-19} \text{ cm}^2$, Figure 5, which was the single value used in our simulations.

The second limitation in our computer simulation was that only one species could be desorbed at a time per area. The computer model was able to add layers of different species to the surfaces of objects, but the desorption of each layer occurred in sequence, one layer (and therefore, one species) at a time. This required the first layer to be depleted before the next layer could begin to desorb.

Because the desorption of each layer of species occurred sequentially instead of together, it was decided that the computer model should bound the problem by simulated

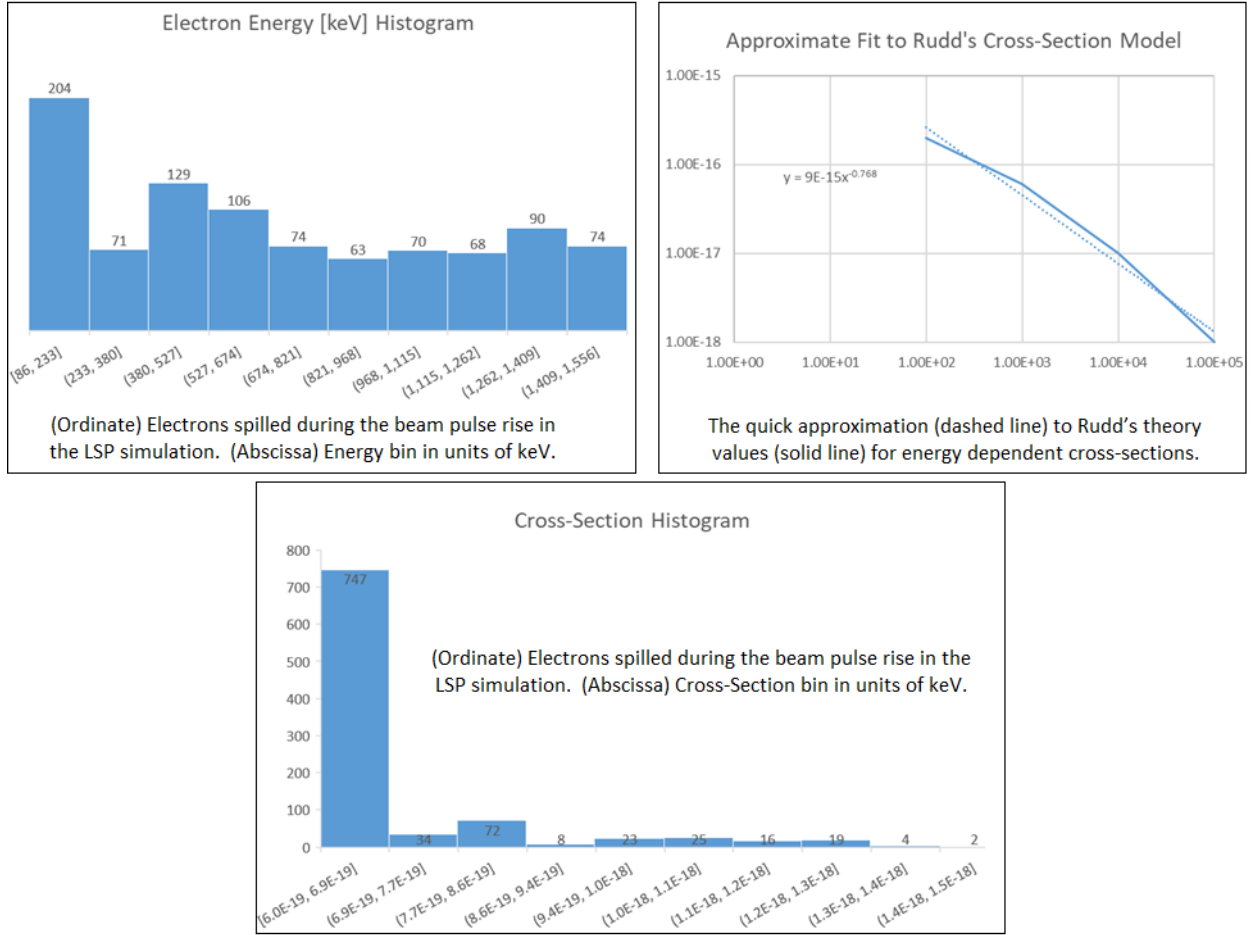

Figure 5:

the effects of a single fast ion species (protons) and then repeat the simulations with a slow ion species (singly ionized water).

Beam Transport

Beam transport results are shown in Figures 6-13, while the effect on the RMS radius at $z = 724$ cm downstream from the cathode shown in Figure 14. At 724 cm, the electron beam has zero convergence. Since the electron beam also has zero convergence as it enters the final focus, these become point-to-point, parallel-to-parallel images. See [1, 2] for further reading.
